**A b s t r a c t.** The results of the experiments showed that the P treatment considerably enhanced the Zn-binding capability of acid soil. The contribution of ortho- and pyro-P to Zn binding was that they changed the structure of humus ligands in the sorbing metal-humus complexes. This was clearly demonstrated with the Fe-HA complex as a simulator of soil sorbent. New double carbon-carbon and phosphorus-oxygen bonds were discovered in the P-modified humic ligand of the Fe-HA complex. Their accumulation provided an explanation for the enhancement of Zn binding by P-treated soil. In addition to P=O bonds, the C=C bonds should also be considered as functional groups capable of metal ion binding. Because of the greater number of electron-donor groups in the pyro-P-modified humus ligand, the pyro-P-treated soil bound Zn more firmly than the ortho-P-treated one. The dissimilar structure of the control and ortho-, pyro-P-modified humus ligands had a direct relationship with the capability of microflora to adapt to the rising Zn pollution of soil. As compared with control, toxic action of Zn compounds was even enhanced by ortho-P although its addition to soil promoted the Zn binding. On the contrary, pyro-P addition to soil reduced the toxic action of Zn compounds. Consequently, the capability of soil to bind external Zn into inert and nontoxic compounds depends on the structural features of humus ligands in surface metal-humus complexes which are of a great importance as sorption barriers.

**K e y w o r d s:** humus ligand structure, phosphate fertilizers, zinc binding

### INTRODUCTION

The capability of soil to bind external chemical compounds is mainly determined by reactions that occur at the solid-liquid interface. These reactions are controlled by the sorbent properties. Earlier studies (Borgaard *et al.*, 1990; Gunjigake and Wada, 1981; Gerke, 1993) showed that soil metal-containing compounds, especially those of iron, are

important in the binding of anions, such as phosphate (P), and cations, such as Zn. Barrow (1986), Kudeyarova and Semenyuk (1999), Xie and MacKenzie (1990) showed that soil treatment with both ortho- and pyro-P may contribute to the enhancement of the Zn binding. It follows that preceding P binding modifies the structure of sorbing surfaces and thereby influences the subsequent binding of Zn. However, the relationship between P-induced surface changes and the capability of soil to bind external metals remains largely unexplored. Soil solids as sorbents for P are extensively covered with humus molecules and thus exhibit the properties of the metal-humus complexes.

There is consequently a need to examine structural features of metal-containing humus compounds under treatment with ortho- and pyro-P. Much attention should be given to high P additions because the use of them is the primary means of overcoming soil microzonality and simulating soil conditions for acceleration of chemical reactions at the soil particles – phosphate solution interface. As it is known, soil P is usually distributed heterogeneously and is rather frequently in high quantities. Especially, the high total P sites are representative in heavily P-fertilized soils.

Properties of soil humus substances (HS) are of crucial importance to influence the bioavailability of metals (Mendonça and Rowell, 1996; Narwal and Singh, 1999). Composition of soil microflora is primarily a function of substrate. Polysaccharides rank among the most essential constituents of soil humus (Lobartini and Tan, 1988). Because of this the preference was given to the amylolytic community to make sure that the toxicity of the Zn compounds in polluted soil can vary significantly with the humus properties.

The aims of the research were: (1) to reveal the changes induced by ortho- and pyro-P in the structure of Fe-containing humus sorbents, and (2) to show their effect on extractability and toxicity of the resulting Zn compounds in a range of Zn additions to soil.

#### MATERIALS AND METHODS

A soil sample was taken from the humus horizon of a grey forest soil (humic luvisols). The chemical parameters of the initial soil were the following:  $\text{pH}_{\text{KCl}} = 4.57$ , base saturation degree – 50 %, total carbon content – 1.3 %, content of total and organic P in the 0.1N NaOH extract – 34.7 and 31.4 mg/100 g, respectively. After sampling, the soil was air-dried and crushed to pass through a 1-mm sieve. The levels of Zn additions to soil were 0, 1, 2, 5, 10, 20, 50, 100, 200, 500 mg Zn/100 g. Zinc was added to original soil and soil treated with  $\text{KH}_2\text{PO}_4$  or  $\text{K}_4\text{P}_2\text{O}_7$  at the rates of 0, 5.5, 21.8, 65.5 and 174.5 mg P/100 g. High additions of both Zn and P were used to simulate the microzonal accumulation of chemicals in soil. After 1 day of incubation at 25 °C and moisture content adjusted to 55% WHC, all the soil samples were divided into two parts.

One part of the soil samples was dried in air and subsequently used for chemical analyses. Zinc was extracted with 0.1 N  $\text{NH}_4\text{Cl}$  (1:80, soil to solution ratio) and its concentration in the extract was measured using the atomic absorption method with a Perkin-Elmer instrument. The 0.1 N NaOH soil extracts (1:20, soil to solution ratio) were used: (1) to measure the concentrations of soluble Fe and P, (2) to determine optical density (spectrophotometrically at 400 nm), (3) to record electronic spectra of alkali-soluble HS in the region from 200 to 800 nm using the UV-VIS Specord spectrophotometer, (4) to compare control and P-modified alkali-soluble HS for the amount of C=C bonds using the test with permanganate solution (the volumes of 0.1 N NaOH extracts expended to decolourize 10 ml of 0.001 N  $\text{KMnO}_4$  were noted).

To determine the total contents of Fe and P in 0.1 N NaOH extracts, the extract aliquots were amalgamated with a mixture (3:1) of  $\text{H}_2\text{SO}_4$  and  $\text{HClO}_4$ . The concentration of Fe was measured using the atomic absorption method. The concentration of P was determined in accordance with Murphy and Riley (1962). To precipitate HA, the 0.1 N NaOH extract from the original soil was acidified with dilute HCl to pH 1.3–1.5. The HA separated was treated with  $\text{FeCl}_3$  to prepare Fe-HA complex. The  $\text{FeCl}_3$  treatment provided C:Fe ratio of 1:6. The complex prepared was treated for five weeks with  $\text{KH}_2\text{PO}_4$  and  $\text{K}_4\text{P}_2\text{O}_7$ . The P solution was added to the Fe-HA complex to have a C:P ratio of 1:12. The value of pH for each system was 4.1. Control complex and P-modified organic solids were used for the infrared examination (KBr – technique) using the Specord M-80 spectrophotometer.

The second part of the soil samples after 1 day of incubation was used for microbiological testing in accordance with the technique of Guzev *et al.* (1980). Each sample was subdivided into six equal portions to be placed in six Petri dishes. Soil surfaces in Petri dishes were coated with starch to stimulate soil amylolytic microflora. Three weeks after the soil incubation at a constant temperature and moisture, the identification of amylolytic species was carried out together with visual estimation of the area occupied by each species.

#### RESULTS AND DISCUSSION

Table 1 shows that P treatment of soil considerably decreased the extractability of Zn by 0.1 N  $\text{NH}_4\text{Cl}$ . That is, the capability of soil to bind external zinc increased under the influence of P. The degree of Zn binding was directly dependent on the P content in soil and was higher when pyro-P was added.

As shown in Fig. 1, the P treatment level had a different effect on the reactivity of soil Fe-containing humus surfaces. Thus, P added at a rate of 5.5 mg/100 g to Zn-control and

**Table 1.** Soluble Zn in 0.1 N  $\text{NH}_4\text{Cl}$  extract depending on Zn and P addition, % of the amount added

slightly Zn-polluted soil promoted the increase in the extractability of Fe by 0.1 N NaOH (Fig. 1A). On the contrary, P (especially pyro-P) added to soil at a rate of 174.5 mg/100 g decreased extractability of Fe independently of Zn pollution level. Iron atoms in highly P-saturated HS were more strongly held by chemical bonds to pass into alkali solution, indicating that some structural changes were induced by P in sorbing compounds. It is apparent that the degree of Fe extractability was governed by the amount of P incorporated into humus macroligand (Fig. 1B).

The colour of 0.1 N NaOH extract became more and more dark as the soil's total P increased (Table 2). So, it is apparent that chromophore groups accumulate in humus molecules, mainly in the HA fraction. Test results for the C=C bonds showed (Table 3) that the volume of 0.1 N NaOH extract required to decolourize KMnO<sub>4</sub> solution was smaller if humus molecules were P-modified. This test demonstrates the increase in the number of double carbon-carbon bonds in P-modified HS. Since aromatic cores are

not able to decolourize permanganate solution, it is evident that additional C=C bonds fell within the ring side chains.

The electronic spectra (Fig. 2) showed the pronounced effect of P on the electron energy state in the extractable HS. Judging from the increased excitability of the molecular

electronic system by UV radiation, P (pyro-P to a greater degree) increased the mobility of electrons in the humus molecules. This fact suggests the P-induced structural modification of the molecules. The P-induced spectral changes are most pronounced in the short-wavelength region of UV spectrum (210–230 nm). The absorption band in this region is attributed to the  $n \rightarrow \pi^*$  – transition of  $\pi$ -electrons of the C=C bonds. Bathochromic band shift observed in the spectra of P-treated HS can be indicative of the occurrence of additional C=C bonds in the side chains. This is consistent with the results of chemical test (Table 3).

Another P-induced spectral change was observed in more long-wavelength UV region (250–350 nm) (Fig. 2). The second (slight) absorption band in the UV region of spectrum can be attributed to the  $n \rightarrow \pi^*$  – transition of  $n$ -electrons possessed by the nucleophilic atoms (oxygen, for one, in the C=O group and heteroanalogs). Hypsochromic shift of this absorption band in the spectra of

P-modified HS could probably be due to the occurrence of the P=O groups which are more polar than the C=O groups.

The experimental results clearly demonstrate the P-induced changes in the structure of humus molecules. The changes observed suggest that there is an accumulation of both additional C=C groups and new O-containing (probably P=O) groups. To confirm this suggestion, the Fe-HA complex was tested as the metal-humus sorbent for P anions. Figure 3 shows that control and P-modified complex solids differed structurally. There are the absorption bands at 1610 and 1402  $\text{cm}^{-1}$  in the control IR spectrum (Fig. 3B) which correspond to the coordinated C=O group (Bellamy, 1975). The P treatment of complex resulted in the disappearance of these frequencies. At the same time, some new absorption bands arose in the spectra of the Fe-HA complex treated with ortho- and pyro-P (Fig. 3C and D). Among them are the bands in the range from 1340 to 1170  $\text{cm}^{-1}$  which can be attributed to the vibration frequencies of the P=O groups having the dissimilar surroundings. Besides, there is the absorption band at 1664 or 1646  $\text{cm}^{-1}$  which can be attributed to the vibration frequency of the C=C groups.

The data obtained proves the possibility of formation of new double carbon-carbon and phosphorus-oxygen bonds in the P-modified HA ligand of the Fe-containing complex through the substitution of prior carbonyl groups. New C=C and P=O bonds, as having a free pair of  $\pi$ - and  $n$ -electrons respectively, should be considered as electron-donor (functional) groups. Their formation could be responsible for the enhancement of the Zn binding by the P-treated soil.

**Fig. 2.** Electronic spectra of alkali-soluble HS (0.1 N NaOH as a reference): 1) P- control soil, 2) ortho-P-modified, 3) pyro-P- modified (P addition to soil is 174.5 mg P/100 g).

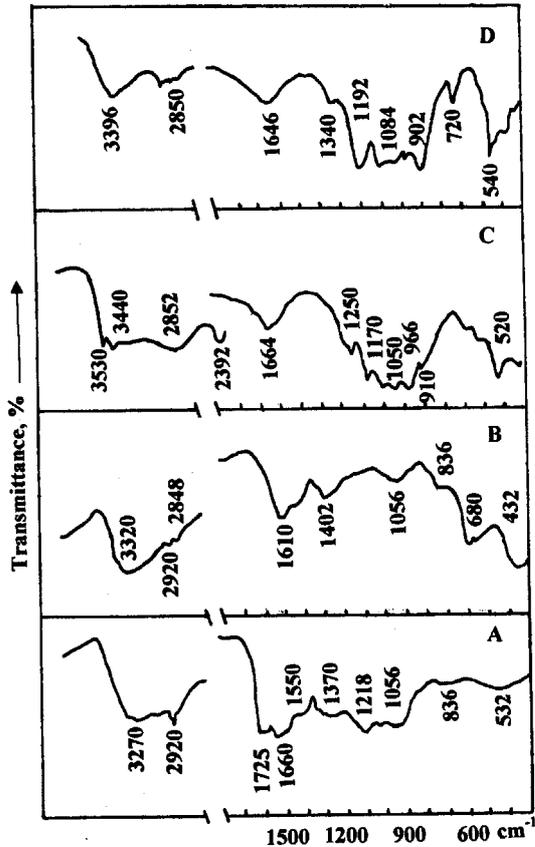

Fig. 3. IR – spectra: A) HA, B) Fe-HA complex, C) ortho-P-treated complex, D) pyro-P-treated complex.

The possible contribution of the C=C groups to Zn binding is supported by experimental data on the Fe binding (Fig. 3A and B). Thus, the absorption band at 1660 cm<sup>-1</sup> corresponding to the C=C vibration is only observed in the IR spectrum of initial HA. In the spectrum of the FeCl<sub>3</sub>-treated HA this band is absent but there is the absorption band at 432 cm<sup>-1</sup> which can be attributed to Fe-C vibration (Bellamy, 1975). Spectral features testify to the fact that the C=C groups are capable of metal binding.

As for the P=O groups, it is known that phosphoryl compounds are more capable of metal complexation than carbonyl ones. This fact is in agreement with the data on Zn binding by P-treated soil (Table 1). As is evident from the Table 1, the pyro-P-treated soil bound Zn more firmly than the ortho-P-treated soil. Figures 3C and D show that the ortho- and pyro-P-modified humic ligands exhibited dissimilar infrared features, mainly in the region of 1340–1170 cm<sup>-1</sup> which can be assigned to P=O vibrations. There were two absorption bands in this region of each discrete spectrum. This fact is probably indicative of two P isomers. Besides, the different P=O vibration frequencies in the IR

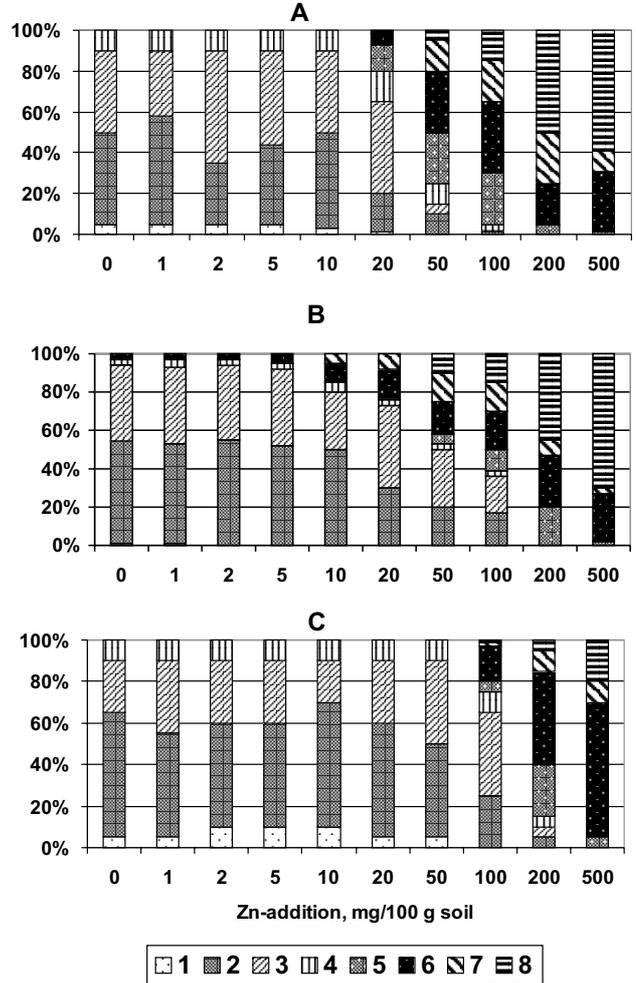

Fig. 4. The composition of amylolytic community depending on Zn and P addition to soil (%): A) P – control soil; B) ortho-P, 174.5 mg P/100 g soil; C) pyro-P, 174.5 mg P/100 g soil; 1) *Streptomyces*; 2) *Humicola*; 3) *Oidiodendron*; 4) *Actinomucor*; 5) *Verticillium*; 6) *Penicillium* sp.; 7) *Pen. vermiculatum*; 8) *Pen. funiculosum*.

spectra of the ortho- and pyro-P-modified humic ligands suggest the dissimilarity of substitutes at P atoms.

The dissimilar arrangement of ortho- and pyro-P-modified humic acid ligand in Fe complex would be expected to influence the toxicity of the Zn compounds resulting from the Zn additions to P-treated soil. The toxicity of heavy metal compounds may be shown by the changes in species composition of native active communities of microorganisms. The approach developed by Guzev *et al.* (1980) allows the study of the species succession resulting from the appearance of harmful products in polluted soil.

Figure 4 shows that the treatment of soil with ortho- or pyro-P produced a strong but dissimilar effect on the capability of amylolytic microflora to adapt to a rising Zn

pollution level. So, ortho-P in no way reduced the stress caused by Zn pollution of soil even though it contributed greatly to the Zn binding (Table 1). On the contrary, the ortho-P treatment enhanced the toxic effect of Zn. Some colonies of *Pen. vermiculatum* emerged in the P-treated soil at a rate of 10 mg Zn/100 g. At the same time, in P-control soil such species emerged at a rate of 50 mg Zn/100 g soil. It should be also noted that certain colonies of *Penicillium* species (*Pen. sp.*) appeared in soil at a zero level of Zn pollution but with 174.5 mg P/100 g. This fact suggests that the ortho-P-modified HS alone might account for the appearance of *Penicillium* microflora.

The effect of pyro-P differed from that of ortho-P on the toxicity of Zn compounds to amylolytic microflora (Fig. 4). In comparison with ortho-P, pyro-P at a rate of 174.5 mg P/100 g contributed to the considerable widening of the homeostasis zone of the native soil amylolytic community (to Zn level of 100–200 mg/100 g). Referring to Figs 2 and 3, the humic ligand transformations induced by ortho-P and pyro-P resulted in the formation of structurally dissimilar products. The results, thus, prove that the toxicity of Zn compounds in the Zn-polluted soil greatly depended on structural features of humus ligands in sorbing HS, namely, on the number and specificity of the functional groups as well as their surroundings.

#### CONCLUSIONS

The degree of Zn binding by acid soil considerably enhanced under the treatment with ortho-P and especially pyro-P. The contribution of P to Zn binding was that they changed the structure of humus ligands in the sorbing metal-humus complexes. This was clearly demonstrated with Fe-HA complex as a simulator of soil sorbent. New double carbon-carbon and phosphorus-oxygen bonds were discovered in the P-modified humic ligand of Fe-HA complex. Their accumulation provided an explanation for the enhancement of Zn binding by P-treated soil. In addition to P=O bonds, the C=C bonds should be also considered as functional groups capable of metal ion binding. Because of the greater number of electron-donor groups in the pyro-P-modified humus ligand, the pyro-P-treated soil bound Zn more firmly than the ortho-P-treated one. Dissimilar structure of the control and ortho-P-, pyro-P-modified humus ligands had a direct relationship to the capability of micro-

flora to adapt to a rising Zn pollution of soil. As compared with control, the toxic action of Zn compounds was even enhanced by ortho-P although its addition to soil promoted the Zn binding. On the contrary, pyro-P addition to soil reduced the toxic action of Zn compounds. Consequently, the capability of soil to bind external Zn into inert and nontoxic compounds depends on the structural features of humus ligands in surface metal-humus complexes which are of a great importance as sorption barriers.
